Abstract

Introduction: One of the most common neurologic disease in Acquired Immunodeficiency Syndrome (AIDS) caused by Human Immunodeficiency Virus (HIV) is represented by progressive multifocal leukoencephalopathy (PML), being caused by John Cunningham (JC) polyoma virus.

Case presentation: We report a case of a 27 years old women, HIV-positive since childhood, under specific antiretroviral therapy with good adherence to it in that period but starting with adolescence adherence to highly active antiretroviral therapy (HAART) decreased. In this context her HIV viral load increased to a 690.000 copies/ml, and CD4 collapsed at 57 cells/mmc. She presented in our clinic with ataxic left hemiparesis, truncal ataxia and left hemi-hypoesthesia. Cerebrospinal fluid (CSF) showed a slightly pleocytosis and polymerase chain reaction performed from CSF diagnosed John Cunningham (JC) virus. Once diagnosis established, we reinitiated HAART, but some neurologic disorders persisted like difficulty of the left upper member, having the modified Rankin scale (mRS) of 5. The patient started a multidisciplinary rehabilitation (MDR) treatment, specifically adapted. It consisted of 4 sessions of neuromotor treatments, 20 sessions of massages, and 12 sessions of occupational therapy. According to MDR, the patient improved the ataxic walking, without support, presenting an improvement mRS of 3.

Conclusions: AIDS patients with PML could require a prolonged MDR treatment for neurological disorders and rehabilitation treatment promptly should be applied when such diagnosis is suspected.

Key words: progressive multifocal leukoencephalopathy, human immunodeficiency virus, neurological disorder, multidisciplinary rehabilitation,
improved at the end of this study, some degree of disability still remains and many neurological regressions were reported (15-19). The area from central nervous system most affected by PML is parieto-occipital white matter. More profound, white matter showed single or multiple lesions without mass effect and magnetic resonance imaging (MRI) sustain the hypointense on T1-weighted images and hyperintense on T2-weighted together with fluid-attenuated inversion recovery (FLAIR) sequences (20).

CSF is usually normal, but sometimes pleocytosis less than 20/μL can occur and protein levels may be slightly elevated (20). Because there is no specific anti-JC treatment, some patients have experienced spontaneous improvements with highly active anti-retroviral therapy (HAART) (4-6). HAART is a very potent regimen for HIV-AIDS patient which initially included three classes of medication: protease inhibitors associated with nucleoside reversetranscriptase inhibitory and nonnucleoside reversetranscriptase inhibitors. Therefore, the dynamics of neural plasticity in HIV-positive patients with PML are still unknown. The present case report describes the positive effect of MDR therapy in a HIV-positive patient with PML.

Case presentation
We report a case of a 27 years old women, diagnosed with HIV at age of 3, with different diseases in her childhood (i.e. extrapulmonary TB, recurrent bacterial pneumonia, recurrent parotiditis, chronic diarrhea, chronic hepatitis B, and oral candidiasis). After her HIV diagnosis, the patient was under specific antiretroviral therapy, with a good adhesion in childhood but with decreased adherence to HAART (i.e. lopinavir/ritonavir in associating with zidovudine/lamivudine) in adolescence. In evolution her HIV viral load increased to a 690,000 copies/ml, and CD4 collapsed at 57 cells/mmc. At clinical and neurologic examination, the patient was awake but drowsy and oriented to time, place, and person. In this context she was hospitalized conscious, having coordination normal on the right side, whereas some ataxia was recorded on the left, with cerebellar dysarthria, diplopia at distance, ataxic left hemiparesis, truncal ataxia, and left hemihypoesthesia. The patient was further bedridden. Cerebrospinal fluid (CSF) examination evidenced a slightly pleocytosis (10 cells/mmc), with no other changes. Polymerase chain reaction (PCR) performed from CSF evidenced presence of JC virus. Other etiology like Toxoplasma, Cryptococcus, Mycobacterium tuberculosis, gram positive or negative bacteria and fungi were excluded by specific CSF examination. Cranio-cerebral MRI examination performed before and after administration of intravenous contrast showed confluent areas of hyperintense signal T2-FLAIR/hypointense T1, without restriction of diffusion, or contrast enhanced, symmetric in the periventricular white matter with subcortical bilateral extension. Lesions with the same characteristics were described in the cerebellar hemispheres, with a greater extension in the left cerebellar hemisphere. It also showed an inactive communicating hydrocephalus, probably induced by the aqueductal stenosis caused by the adherences (Figure 1). In this case clinical manifestation, biological and imaging changes sustained the PML diagnosis.

Fig. 1. Confluent areas of hyperintense signal T2-FLAIR/hypointense T1, without restriction of diffusion, symmetric in the periventricular white matter with subcortical bilateral extension.

After the established diagnosis, a symptomatic treatment was introduced and further reinitiated HAART (i.e. darunavir/ritonavir, raltegravir, associated with zidovudine/ziagen), but some neurologic disorders persisted like orthostatism and walking with great difficulty, supporting by another person, coordination and balance disorders, showing partial recovery in speech disorders and using with
difficulty the left upper member. The degree of
disability was measured using the modified Rankin
scale (mRS) in which after 5-years of follow-up, the
patient presented a mRS of 3 (moderate disability;
requires some help, but able to walk unassisted-
according with mRS) from initially 5 (severe
disability; requires constant nursing care and
attention, bedridden, incontinent, according to
mRS). The mRS present a score from 0 to 6 in
which 0 are patients with no symptoms and 6 were
death persons (20).
In this context, the patient started a MDR treatment
according to a neurologist and specialist in balneo-
rehabilitation. The treatment was applied 5 years, 4
days/week, specifically adapted having the aims:
muscle-ligament trophicization, recovery of the
coordination of the left upper member function in
order to increase muscle strength. Moreover, the
program also included 4 sessions of neuromotor
treatments, 20 sessions of massages, and 12 sessions
of occupational therapy. The program ensures the
more passive mobilization of the fingers, increasing
the patient’s ability in grasping in a functional
position, according to special guiding techniques.
A control cerebral MRI was performed after 4 years
which shows the sequelae of the lesions previously
described, the same hydrocephalus, but with an
evident cortical atrophy (Figure 2). Images
 correlated with the physical improvement but also
with the cognitive decline and behavior
disturbances. The patient has been also showed an
increased CD4 to 430/ mmc and became
undetectable 7 months after HAART resumption.

The patient improved the ataxic walking, performing
short distance walking, without support, with an
improved mRS of 3, without any severe sequelae.

Discussion
Worldwide epidemiology and morbidity by different
infectious diseases changed over the last years. In
some diseases like boutonese fever, shigella or
salmonella, evolution is related with environmental
factors (21-24), in other diseases evolution is related
with outbreaks that can appear in absence of
vaccination (25–28). In other diseases like TB or
HIV evolution and mortality changed over the years
according with early or late diagnosis and also with
availability and adherence of specific treatment (29-
34).
If, at the onset of the HIV pandemic, both physicians
and patients were concerned only with prolonged
survival, as this was achieved through complex
treatment and specialized care, new clinical and
therapeutic challenges are emerging for these
patients. Currently, the medical approach of HIV-
positive patients has changed. The care only by the
infectious doctor has been switched to
multidisciplinary approach, according with health
problems of these patients. In our case neurologic
and balneo-rehabilitation support were essential for
treatment strategy.
PML showed to be a disease of a white matter cause
by JC virus in which diagnosis can be made by using
brain imaging investigation and even biopsy (35,36).
Although there is no anti-JC treatment until present,
in HIV positive patients have been showed an
improvement along HAART. In HIV, before
HAART survival for PML at one year was only
10%, but in the last years survival is at least 50%
(20,37,38). The new biologic therapy (i.e. rituximab,
efalizumab or natalizumab), for chronic diseases like
rheumatoid arthritis, psoriasis, multiple sclerosis or
Crohn’s disease contribute to appearance of PML in
other diseases, non-HIV related (39). Although
survival increased, long term neurological sequelae
in PML patients were not very well known. As long
as PML is not a curable disease, by an specific
treatment, persistence of immune restoration is
essential for survival of these patients. Many
patients from literature achieving this goal maintain
this status and no reactivation or relapses were
noticed (40, 41).
In developing rehabilitation strategies for PML in
HIV-positive patients, both caregivers and
professionals must take into consideration their
external support (42). The attitude and rehabilitation program should be constructed similar with those for patients with cancer, or multiple sclerosis (43,44). Our study sustain the introduction of MDR program in HIV-positive patients, especially when is complicated by neurological disorders such as PML. At the end of the treatment, our patient showed better performances at left upper member, despite the ataxic left hemiparesis deficits. We can further admit that clinical PML symptoms were ameliorated by physical rehabilitation, although the treatment was applied after few months of symptoms appearance. The increased activation could be recorded by neurological abilities or hydrokinetotherapy (7), along with climatic factors among the effects of balneal cures which influence the quality of life of patients (8, 11), admitting the idea of the consultants’ professionalism and experience in the management of changes specific to health systems (9).

In this context, we only can assume that MDR might be used by routine in the practice of HIV-positive patients like in different other disability disorders. Although the number of patients remains limited, physical exercises have been showed to contribute an improving aerobic capacity, along with immune restoration in HIV patients (45,46).

Therefore, in patients with HIV and PML the role of physical rehabilitation could play an important role in achieving their health along with integration in their communities.

Conclusions

Although our study showed that MDR treatment can be highly encouraging in HIV-positive patient with PML, additional studies are demanded in order to achieve this aim. Therefore, larger studies should be acquired in order to identify potential candidates for achieving rehabilitation outcome.
